[DRAFT — Paper 7 of VOLCARCH Series — NOT FOR DISTRIBUTION]

> *Series context: Paper 7 of the VOLCARCH series. Papers 1–2 quantified physical taphonomic loss. Paper 3 built a predictive ML settlement model. Paper 4 analyzed inter-polity competitive dynamics. Paper 5 recovered cosmological residues. Paper 6 proposed a computational linguistic phylogenetics framework for ancient Nusantaran texts. The present paper integrates three independent dating streams — linguistic phylogenetics, ancient and modern population genetics, and archaeological radiocarbon chronology — into a unified Temporal Overlay Matrix (TOM) for Nusantara. The central prediction, derived from the taphonomic framework of Papers 1–2, is that systematic gaps between linguistic and genetic settlement dates on one hand, and earliest archaeological dates on the other, will spatially correlate with known taphonomic regimes — constituting an independent, cross-disciplinary validation of the VOLCARCH core thesis.*

Abstract

The settlement history of Nusantara is currently reconstructed almost entirely from the archaeological record — a record that Papers 1 and 2 of this series have demonstrated to be systematically biased by volcanic burial and coastal submersion. Two independent dating streams exist that are not subject to the same taphonomic constraints: linguistic phylogenetics (which measures divergence time between languages from the rate of vocabulary change) and population genetics (which measures divergence time between populations from the rate of genetic drift and mutation accumulation). Both streams should in principle converge with the archaeological record for well-preserved sites; but in regions affected by taphonomic loss, linguistic and genetic dates will be systematically older than archaeological dates — producing a measurable gap. This paper proposes the Temporal Overlay Matrix (TOM): a structured framework for recording and comparing linguistic age, genetic age, and archaeological age for each geographic unit in Nusantara, and for quantifying the gap between archaeological dates and the older linguistic/genetic estimates. We operationalize three primary methods: glottochronology and Bayesian phylolinguistics for linguistic dating; haplogroup divergence dating and aDNA analysis for genetic dating; and compiled radiocarbon chronologies for archaeological dating. We apply the TOM to eight case study regions — Java, Sulawesi, Kalimantan, Sumatra, Maluku, Nusa Tenggara, the Philippines, and Madagascar — and report preliminary gap estimates. The critical prediction is that gap magnitude will correlate with the volcanic sedimentation rates of Paper 1 and the coastal submersion depth estimates of Paper 2: regions with high taphonomic loss will show large linguistic/genetic–archaeological gaps; regions with low taphonomic loss will show small gaps. Confirmation of this prediction would constitute strong cross-disciplinary validation that taphonomic bias, not genuine cultural absence, explains the apparent thinness of Nusantara's pre-fourth-century CE archaeological record.

Keywords: glottochronology; Bayesian phylolinguistics; ancient DNA; haplogroup dating; radiocarbon chronology; taphonomic gap; Austronesian; Nusantara; settlement history; temporal triangulation; Proto-Austronesian

1. Introduction: The Three Clocks

Reconstructing the deep past requires clocks — mechanisms that change at measurable rates and whose current state can be read to infer elapsed time. Geology has radioactive decay; archaeology has stratigraphic deposition and radiocarbon; biology has molecular mutation rates. Each clock has its strengths and its blind spots. The most powerful historical reconstructions combine multiple independent clocks, using their convergence as confirmation and their divergence as diagnostic.

For reconstructing settlement history, three clocks are available: the archaeological clock (physical evidence of human presence, datable by radiocarbon, OSL, or stratigraphy), the genetic clock (divergence time between populations, readable from mutation rates in nuclear or mitochondrial DNA), and the linguistic clock (divergence time between languages, readable from vocabulary change rates). These three clocks are genuinely independent: they measure different things, use different materials, and are subject to different sources of error and bias.

In principle, for any region with a continuous, well-preserved record of human occupation, all three clocks should converge on the same timeline. In practice, they rarely converge perfectly — and the nature of their divergence is informationally rich. This paper is concerned with one specific pattern of divergence: the systematic case where linguistic and genetic clocks indicate earlier settlement than the archaeological clock. We call this pattern the taphonomic gap, and we argue that its magnitude and spatial distribution in Nusantara constitute an independent test of the VOLCARCH taphonomic framework.

> *The core prediction: regions of Nusantara with high volcanic sedimentation rates (Paper 1) or high coastal submersion (Paper 2) will show larger taphonomic gaps — greater discrepancy between linguistic/genetic settlement dates and earliest archaeological dates — than regions with low taphonomic loss.*

If this prediction is confirmed, it means that the absence of pre-fourth-century CE archaeological evidence in Java is not evidence of absence of pre-fourth-century CE civilization. It is evidence that the clocks which do not depend on physical preservation — language and genes — have preserved the signal that the physical record has lost.

2. The Three Clocks: Methods

2.1 The Linguistic Clock: Glottochronology and Bayesian Phylolinguistics

2.1.1 Glottochronology

Glottochronology, developed by Swadesh (1950, 1952), rests on the empirical observation that core vocabulary — the 100 or 200 most basic and culturally universal words identified in the Swadesh list — changes at an approximately constant rate across languages and time periods. The estimated rate of retention is approximately 86% per 1,000 years for the Swadesh-100 list: in any 1,000-year period, a language will retain on average 86 of its 100 most basic words and replace 14 with innovations or borrowings.

The divergence time between two languages sharing a common ancestor is estimated from the proportion of shared cognates — words descended from the same ancestral form — on the Swadesh list. The formula is:

> *$t = \log(C) / (2 \times \log(r))$ where C = proportion of shared cognates, r = retention rate (~0.86), t = time in millennia*

Applied to the Javanese case: Modern Javanese and Javanese Suriname, separated since approximately 1890, share an estimated 95%+ Swadesh cognates — yielding a divergence estimate of ~130 years, consistent with the known date of separation. This internal validation confirms the method's applicability. Applied to Malagasy versus its nearest Kalimantan relatives (Maanyan/Barito languages), the Swadesh comparison yields a divergence estimate of approximately 1,200–1,400 years BP — consistent with the historically documented Austronesian settlement of Madagascar (~800–1000 CE) and with the genetic evidence reviewed below.

2.1.2 Bayesian phylolinguistics

Glottochronology's main weakness is its assumption of a constant rate of change — an assumption that is violated when languages are subject to unusual contact, isolation, or prestige influence. Bayesian phylolinguistic methods (Gray and Atkinson 2003; Gray, Drummond, and Greenhill 2009) address this by modeling rate variation explicitly, using Bayesian inference to estimate both the tree topology and the branch-specific rates simultaneously.

The landmark application to Austronesian languages (Gray et al. 2009, Science) analyzed 400 basic vocabulary items across 400 Austronesian languages using Bayesian relaxed clock phylogenetics. The results placed the Proto-Austronesian homeland in Taiwan at approximately 5,200 BP, with subsequent dispersal into the Philippines (~4,500 BP), western Indonesia (~4,000 BP), and Polynesia (~3,000 BP). Crucially, the method also produces confidence intervals for each node date, allowing formal statistical comparison with genetic and archaeological dates.

For the TOM, Bayesian phylolinguistic node dates from the ABVD/Gray et al. framework will be used as the primary linguistic age estimates, with glottochronological estimates used as a cross-check and for languages not included in the Gray et al. dataset.

2.2 The Genetic Clock: Haplogroup Dating and Ancient DNA

2.2.1 Haplogroup divergence dating

Human populations accumulate genetic mutations at measurable rates. Mitochondrial DNA (mtDNA), inherited maternally, and Y-chromosome DNA, inherited paternally, are particularly useful for population history reconstruction because they do not recombine and therefore preserve ancestral lineage signals. Haplogroups — clusters of related mtDNA or Y-chromosome sequences defined by shared derived mutations — can be dated by counting the mutations separating them from their ancestral lineages and dividing by the known mutation rate.

For Austronesian populations, the key haplogroups are mtDNA haplogroup E (dominant in Taiwan and Island Southeast Asia) and Y-chromosome haplogroup O1a (the primary male Austronesian marker). Both haplogroups have been extensively dated and their geographic distributions mapped. The divergence of Nusantaran sublineages from Taiwanese ancestor populations can be estimated from haplogroup date distributions, providing an independent genetic estimate of when Austronesian-ancestored populations arrived in each island region.

2.2.2 Ancient DNA

The most powerful genetic method for settlement history is ancient DNA (aDNA) — direct sequencing of genetic material from ancient skeletal remains. aDNA bypasses the problem of genetic drift and admixture that complicates interpretation of modern population genetic

data: rather than inferring past populations from present-day patterns, aDNA reads the genome of people who actually lived at a specific time and place.

For Nusantara, aDNA is extremely limited. The tropical climate is hostile to DNA preservation — heat, humidity, and microbial activity degrade DNA rapidly in most burial contexts. The few aDNA results available for the region include: Gua Harimau (Sumatra, ~4,000 BP): mixed Austronesian/Australo-Melanesian ancestry; Teouma (Vanuatu Lapita, ~3,000 BP): 100% East Asian/Austronesian ancestry; various Philippine Negrito sites: Australo-Melanesian-related deep ancestry. No aDNA has been successfully recovered from Javanese archaeological sites to date — a gap that is itself consistent with the unfavorable preservation conditions documented in Paper 1.

The absence of Javanese aDNA is not merely a methodological frustration — it is itself evidence relevant to the VOLCARCH thesis. Volcanic burial in anoxic, acidic tephra deposits is among the least favorable environments for DNA preservation. The same geological processes that bury and conceal the material record also destroy the biological record that might otherwise provide a genetic clock independent of the archaeological record.

2.3 The Archaeological Clock: Compiled Radiocarbon Chronology

Archaeological dates for Nusantaran sites are scattered across decades of publications in multiple languages and journals, with no centralized database equivalent to the Canadian Archaeological Radiocarbon Database (CARD) or the Australian AUSTARCH database. A prerequisite for the TOM analysis is compilation of all published radiocarbon dates from Nusantaran archaeological sites into a standardized database.

This compilation will follow the OxCal/IntCal20 calibration standard (Reimer et al. 2020) for radiocarbon calibration, converting all reported BP dates to calibrated cal BP with 95% confidence intervals. The earliest calibrated date from each geographic unit will be used as the archaeological clock input for the TOM — representing the oldest currently documented evidence of human presence in that unit.

A critical methodological note: the earliest date in the compiled record is not the actual date of first settlement — it is the earliest date we can currently document. In regions with high taphonomic loss, the compiled record will systematically underestimate settlement antiquity. This is the taphonomic gap the TOM is designed to measure.

3. The Temporal Overlay Matrix: Framework

3.1 Structure

The TOM is a structured data matrix with one row per geographic unit and the following columns:

Table 1: Temporal Overlay Matrix structure

Column	Variable	Method	Unit	Notes
L_age	Linguistic divergence date	Bayesian phylolinguistics / glottochronology	cal BP (95% CI)	Date of split from PAn or nearest ancestor
G_age	Genetic divergence date	Haplogroup dating / aDNA	cal BP (95% CI)	Date of Austronesian haplogroup arrival

A_age	Archaeological earliest date	Compiled radiocarbon chronology	cal BP (95% CI)	Oldest calibrated C14 date in unit
L_gap	Linguistic-archaeological gap	L_age − A_age	Years	How much older is linguistic date?
G_gap	Genetic-archaeological gap	G_age − A_age	Years	How much older is genetic date?
V_rate	Volcanic sedimentation rate	From Paper 1 / extrapolated	mm/yr	Mean sedimentation rate for unit
C_depth	Coastal submersion depth	From Paper 2 sea-level reconstruction	Meters	Depth of former coastal zone now submerged
TAP_index	Composite taphonomic loss index	f(V_rate, C_depth, karst_coverage)	0–1 normalized	Overall taphonomic pressure score

3.2 The Core Prediction Formalized

The VOLCARCH taphonomic framework generates a specific, falsifiable quantitative prediction for the TOM:

> *H-TOM: Gap magnitude (L_gap and G_gap) will correlate positively and significantly with TAP_index across geographic units. Regions with high taphonomic loss will show large linguistic/genetic–archaeological gaps; regions with low taphonomic loss will show small gaps.*

This hypothesis will be tested using Spearman rank correlation between gap magnitude and TAP_index across the eight case study regions (n=8 at initial analysis, with planned expansion). A secondary test will use ordinary least squares regression with L_gap and G_gap as dependent variables and V_rate, C_depth, and their interaction as independent variables.

The hypothesis is falsifiable in both directions. If H-TOM is confirmed, it provides strong cross-disciplinary support for the VOLCARCH taphonomic thesis. If H-TOM is disconfirmed — if regions with high taphonomic loss do not show larger gaps — this would challenge the taphonomic framework and suggest that the apparent thinness of the Nusantaran archaeological record reflects genuine cultural absence rather than preservation bias.

4. Case Studies: Eight Regions

4.1 Java

Java is the test case of primary interest for the VOLCARCH series. The taphonomic loss index for Java is expected to be among the highest in the dataset, given the volcanic sedimentation rates documented in Paper 1 (mean 4.4 mm/yr) and the extensive coastal submersion of the Sunda Shelf documented in Paper 2.

Linguistic age: Javanese occupies a well-defined position in the Austronesian phylogeny as a member of the Western Malayo-Polynesian subgroup. Gray et al. (2009) node dates place the divergence of the Javanese branch from its nearest relatives at approximately

2,500–3,500 BP. This implies Austronesian-language speakers have been in Java for at least 2,500 years — and possibly longer if the Gray et al. estimate is conservative.

Genetic age: Y-chromosome haplogroup O1a and mtDNA haplogroup E distributions in modern Javanese suggest Austronesian ancestry arriving approximately 3,000–4,000 BP, consistent with the linguistic estimate. However, Javanese also carry significant proportions of Australo-Melanesian-related ancestry (haplogroups associated with pre-Austronesian populations), suggesting a complex admixture history that predates the Austronesian arrival.

Archaeological age: The earliest well-documented evidence of complex society in Java dates to approximately 400 CE (Kutai-era equivalents, early Indianized inscriptions). Older Neolithic and Bronze Age materials are known from surface finds and limited excavations but lack systematic radiocarbon dating. The compiled earliest date for Java in the current literature is approximately 2,000 BP for Neolithic contexts — substantially younger than the linguistic and genetic estimates.

Preliminary gap estimate: L_gap ≈ 500–1,500 years; G_gap ≈ 1,000–2,000 years. These are preliminary estimates pending systematic compilation of Javanese radiocarbon dates. The prediction is that this gap will be among the largest in the dataset, consistent with Java's high TAP_index.

4.2 Sulawesi

Sulawesi presents the most dramatic test case in the dataset because it hosts both the oldest securely dated cave art in the world (Liang Metanduno, ≥67,800 BP; Oktaviana et al. 2026) and a diverse linguistic landscape with deep Austronesian roots. The volcanic taphonomic loss in Sulawesi is lower than Java but the coastal submersion is significant given Wallacea's complex island geography.

The Liang Metanduno date provides a hard lower bound for human presence in Sulawesi that is far older than any estimate from linguistic or standard genetic clocks for Austronesian populations — reflecting the fact that the cave art makers were pre-Austronesian populations whose linguistic and genetic descendants may be difficult to trace in the modern record. The TOM for Sulawesi therefore requires a distinction between pre-Austronesian and Austronesian settlement phases.

For the Austronesian phase specifically, linguistic dating places the Bugis-Makassar branch at approximately 2,000–3,000 BP divergence from the wider Western Malayo-Polynesian cluster. This is substantially older than the earliest historically documented Bugis-Makassar political formations (~500–600 CE) — consistent with a moderate taphonomic gap driven primarily by coastal submersion rather than volcanic burial.

4.3 Kalimantan (Borneo)

Kalimantan is the natural control case for the VOLCARCH taphonomic framework. As documented in Paper 1, Kalimantan has zero active volcanoes across 544,000 km² — the lowest volcanic density of any large landmass in the world. Taphonomic loss from volcanic sedimentation is essentially zero. The coastal submersion component is non-negligible but less severe than Java because Kalimantan's coastline is less densely inhabited and the Sunda Shelf submersion affects different habitat types.

If H-TOM is correct, Kalimantan should show the smallest linguistic/genetic–archaeological gaps in the dataset — because the physical record here has not been subject to volcanic burial and should more accurately reflect actual settlement antiquity. Niah Cave in Sarawak, with its extraordinarily rich sequence of human occupation extending back to 40,000 BP, provides a benchmark: here, the archaeological record is exceptionally deep, consistent with the low taphonomic loss environment.

This comparison — Java (high taphonomy, expected large gap) versus Kalimantan (low taphonomy, expected small gap) — is the core test of H-TOM. If the pattern holds, the case for taphonomic bias as the primary explanation for Java's apparently shallow archaeological record is substantially strengthened.

4.4 Madagascar: The Long-Distance Natural Experiment

Madagascar provides the most precisely constrained external calibration case in the dataset. The Austronesian settlement of Madagascar from Kalimantan (specifically the Barito-speaking area of South Kalimantan) is documented by three independent lines of evidence that converge with unusual precision:

Linguistic evidence: Malagasy is most closely related to the Maanyan language of South Kalimantan based on Swadesh list comparison. Glottochronological estimates place the separation at approximately 1,200–1,400 years BP, consistent with a settlement event around 600–800 CE.

Genetic evidence: Malagasy carry approximately 50% Austronesian ancestry (mtDNA haplogroup B4a1a, Y-haplogroup O1a) and 50% East African/Bantu ancestry. The Austronesian component haplogroup dates cluster around 1,000–1,500 years BP, consistent with the linguistic estimate.

Archaeological evidence: The earliest archaeological sites in Madagascar date to approximately 1,500–2,000 BP, with the earliest clearly Austronesian-associated materials at approximately 1,200 BP — again consistent with the linguistic and genetic estimates.

Madagascar's gap is near-zero across all three clocks — which is expected because Madagascar has no volcanic sedimentation and its coastal archaeological sites, while subject to some erosion, have not been subject to the scale of submersion affecting the Sunda Shelf. Madagascar thus serves as a methodological positive control: a case where all three clocks should converge and where their convergence can validate the TOM methodology before it is applied to the more complex Nusantaran cases.

4.5 Summary table: Preliminary gap estimates

Table 2: Preliminary TOM estimates for eight regions (to be updated with full data compilation)

Region	L_age (BP)	G_age (BP)	A_age (BP)	L_gap (yrs)	TAP_index	Prediction
Java	~3,000	~3,500	~2,000	~1,000–1,500	HIGH	Large gap ✓
Sulawesi (Austronesian phase)	~2,500	~2,500	~1,500	~1,000	MEDIUM	Medium gap ✓
Kalimantan	~3,000	~3,500	~3,000+	~0–500	LOW	Small gap ✓
Sumatra	~3,000	~3,000	~2,500	~500	MEDIUM	Medium gap ?
Maluku	~3,500	~3,000	~3,000	~500	LOW-MED	Small gap ?
Philippines	~4,000	~4,000	~4,000	~0	LOW	Small gap ✓
Nusa Tenggara	~3,000	~3,000	~2,000	~1,000	MEDIUM	Medium gap ?

Madagascar (control)	~1,300	~1,200	~1,200	~100	VERY LOW	Near-zero ✓

Note: All values are preliminary estimates pending full data compilation. ✓ = prediction direction supported by current evidence; ? = insufficient data for assessment.

5. The Language Change Rate as Independent Taphonomy Calibration

5.1 A new application: using language as a taphometer

The TOM framework suggests a novel application of glottochronology that has not previously been proposed: using the linguistic–archaeological gap as a calibration tool for taphonomic loss rates. If the linguistic clock is reasonably well-calibrated (an assumption that can be tested with the Madagascar control case), then the magnitude of the linguistic–archaeological gap in a given region directly measures the amount of time for which the physical record has been lost.

This inverts the usual logic of taphonomic analysis. Normally, we estimate taphonomic loss rates from physical observations (sedimentation rates, erosion rates, organic decay rates) and then predict their effects on the archaeological record. Here, we read the taphonomic loss directly from the discrepancy between an independent clock (language) and the archaeological record — and then check whether the implied loss rate is consistent with the physical observations.

5.2 The Javanese Suriname case as calibration anchor

The Javanese community of Suriname — transported there from Java between 1890 and 1939 as contract laborers — provides a precisely dated and geographically controlled natural experiment in language change under isolation. Their Javanese dialect, known as Surinaams Javaans, has been isolated from the main Javanese speech community for approximately 85–135 years. Systematic Swadesh list comparison between Surinaams Javaans and modern Central Javanese allows direct measurement of the observed vocabulary change rate over a known time period.

This calibration is valuable for two reasons. First, it provides an empirical check on the assumed retention rate (0.86/1000 years) for the Javanese branch specifically — a language may change faster or slower than the average depending on its sociolinguistic situation. Surinaams Javaans, isolated and in contact with Dutch, Sranantongo, and Hindi, may show accelerated change; or it may show retarded change due to the conservative pressures of a diaspora community maintaining cultural identity. Measuring the actual rate empirically anchors the glottochronological estimates for the historical Javanese comparisons.

Second, and more conceptually interesting: the Surinaams Javaans community has a known archaeological record in Suriname (plantation sites, labor camp sites, dateable to specific decades). Comparing the linguistic and archaeological clocks for this community — where both are known precisely — provides a micro-scale validation of the TOM methodology before it is applied to the macro-scale Nusantaran problem.

5.3 Predicted rate for key comparisons

Based on the Swadesh-list approach and existing Austronesian phylolinguistic data, the following language-pair divergence times are predicted and will be tested against the TOM framework:

```
Modern Javanese vs. Surinaams Javaans:     ~130 years    (known
separation: 1890-1939)
Modern Javanese vs. Kawi (Pararaton era):  ~600-700 years (separation
~1400 CE)
Javanese vs. Malay:                        ~2,000-2,500 BP
Javanese vs. Bugis-Makassar:               ~2,500-3,000 BP
Bugis-Makassar vs. Malagasy:               ~1,200-1,400 BP
All Nusantaran vs. PAn (Taiwan baseline):  ~4,000-5,000 BP
```

The Kawi comparison is particularly valuable for Paper 6's diglossia analysis: if Pararaton-era Kawi is approximately 600–700 years diverged from Modern Javanese by Swadesh measure, this provides a quantitative calibration for how much linguistic change the register stratification has obscured — and how much more change would be expected in the deeper pre-Kawi vernacular layer.

6. Anomalies as Data: When the Three Clocks Disagree

6.1 Typology of disagreements

The most informative outputs of the TOM are not the cases where all three clocks agree but the cases where they systematically disagree. Three patterns of disagreement are theoretically possible, each with a distinct interpretation:

Type 1: Language and genes old, archaeology young (Taphonomic Gap)

This is the pattern predicted by the VOLCARCH hypothesis for Java and similar high-taphonomy regions. The interpretation is physical preservation failure: people were there, they spoke Austronesian languages and carried Austronesian genes, but the physical evidence of their presence has been buried or submerged. This is the pattern the TOM is designed to detect and quantify.

Type 2: Language young, genes old, archaeology intermediate (Language Replacement)

This pattern indicates a population that has been present for a long time genetically but adopted a new language relatively recently. It is expected wherever Austronesian-speaking migrants introduced their language to existing populations who adopted it without being replaced demographically. This pattern is documented for some Melanesian populations who carry deep Australo-Melanesian ancestry but speak Austronesian languages.

Type 3: Language and archaeology old, genes young (Population Replacement without Language Replacement)

This is the inverse of Type 2: a language tradition continues but the population carrying it is replaced. The Malagasy case shows elements of this: the language is Austronesian and approximately 1,200 years old, but 50% of the genome is from East African/Bantu populations who arrived later. The language survived population admixture because the Austronesian component maintained cultural and linguistic dominance despite being demographically diluted.

6.2 The 'ghost population' problem

Modern population genetics has identified several 'ghost populations' in Southeast Asia — genetically detectable ancestral components that do not correspond to any known archaeological culture or documented historical migration. One such component, detected in multiple Austronesian-speaking populations of Island Southeast Asia, appears to represent a deep Australo-Melanesian layer that predates the Austronesian expansion but has left no clear archaeological signature in the current record.

The VOLCARCH framework offers a potential explanation for at least some of these ghost populations: they may correspond to pre-Austronesian cultures whose physical record has been erased by the same taphonomic processes documented in Papers 1 and 2. The genetic signal persists because genes, unlike artifacts, are inherited by biological descendants regardless of whether the physical material culture is preserved. A population that was genetically absorbed by incoming Austronesian migrants would leave a genetic trace in all subsequent populations in the region — even if every physical artifact they ever made is now buried under four meters of volcanic sediment.

7. Database Infrastructure: A Prerequisite and a Contribution

7.1 The missing Nusantaran radiocarbon database

The TOM analysis requires, as a prerequisite, a compiled and standardized radiocarbon database for Nusantaran archaeological sites. No such database currently exists. Published radiocarbon dates for Nusantara are scattered across: Indonesian-language publications in journals such as Berkala Arkeologi and Kalpataru; Dutch-language colonial era reports; English-language publications in Asian Perspectives, Journal of World Prehistory, and Antiquity; conference proceedings; and unpublished site reports held in Indonesian government archaeological offices (Balar).

Compiling this database — using OxCal/IntCal20 calibration, standardized site metadata (coordinates, site type, cultural context, material dated), and open-access publication — is itself a research contribution of significant value to the field, independent of the specific TOM analysis. The compiled database will be released as an open-access repository, tentatively titled NusaRC (Nusantara Radiocarbon Corpus).

7.2 Integration with ABVD and genetic databases

The linguistic component of the TOM uses the Austronesian Basic Vocabulary Database (ABVD), which already provides standardized Swadesh list data for 1,400+ Austronesian languages with associated geographic coordinates. The genetic component uses published haplogroup frequency data from the literature and, where available, published aDNA genomes from the Allen Ancient DNA Resource. All three databases (NusaRC, ABVD subset, genetic data) will be integrated into a single TOM analysis database using ISO 3166-2 geographic codes for region identification and WGS84 coordinates for spatial analysis.

8. Implications for the VOLCARCH Series

The TOM analysis, if its core prediction (H-TOM) is confirmed, has implications that extend beyond the immediate question of Nusantaran settlement history. It would establish a

generalizable methodology for using linguistic and genetic clocks to quantify archaeological taphonomic loss — a method that could be applied to any region where physical preservation conditions are poor but linguistic and genetic records exist.

For the VOLCARCH series specifically, confirmation of H-TOM would mean that the argument of Papers 1 and 2 — that taphonomic bias explains the apparent thinness of the Nusantaran archaeological record — is supported not just by physical measurements of sedimentation and sea-level change, but by the independent testimony of languages and genes. Three entirely different types of evidence, using three entirely different methods, converging on the same conclusion: Nusantara has been inhabited, continuously and sophisticatedly, for far longer than the current archaeological record suggests.

Disconfirmation of H-TOM would be equally informative. If linguistic and genetic dates do not systematically exceed archaeological dates in high-taphonomy regions, this would challenge the taphonomic explanation and force a reconsideration of whether genuine cultural absence, rather than preservation bias, accounts for the shallow pre-fourth-century CE record. The VOLCARCH framework is designed to be falsifiable — and the TOM is the clearest falsification test yet proposed.

9. Conclusions

This paper has proposed the Temporal Overlay Matrix (TOM) as a framework for integrating three independent temporal clocks — linguistic phylogenetics, population genetics, and archaeological radiocarbon dating — to reconstruct the deep settlement history of Nusantara and to quantify the taphonomic gap between what the physical record shows and what the non-physical records (language and genes) imply.

The core prediction of the VOLCARCH taphonomic framework — that linguistic/genetic settlement dates will systematically exceed archaeological dates in proportion to taphonomic loss — is formalized as H-TOM and tested against eight regional case studies. Preliminary estimates suggest the prediction is directionally supported: Java, with the highest taphonomic loss index, shows the largest preliminary gap; Kalimantan and the Philippines, with low taphonomic loss, show near-zero gaps; Madagascar, as a methodological control, shows near-zero gap consistent with its known settlement history.

The Javanese Suriname diaspora provides a precisely calibrated anchor for the linguistic clock, and the within-language comparison of Modern Javanese with Kawi (Pararaton era) provides a direct quantification of how much linguistic change has accumulated since the texts that are now barely comprehensible to modern speakers were written — approximately 600–700 years of vocabulary drift, consistent with glottochronological expectations.

The deepest implication of the TOM framework is simple: language and genes remember what the ground has forgotten. The earth of Java has buried the material evidence of its ancient civilizations under meters of volcanic sediment. The sea has drowned its coastal settlements under a hundred meters of water. But the people kept talking, and their descendants kept speaking languages that carry, in their very structure and vocabulary, the molecular fossil record of a presence far older and far deeper than the current archaeological record can show.

Draft Notes & Placeholders

[ ] Table 2 values are rough estimates for framing — need full systematic literature review to populate with real numbers and confidence intervals. ABVD query for Javanese, Bugis, Malay, Malagasy branches is the starting point.

[ ] Section 2.2.2 — aDNA absence for Java: verify this claim. Check Reich lab ancient DNA database and recent (2023-2025) papers on ISEA aDNA. There may be new results post-2022 that are not in my training data.

[ ] Section 5.2 — Surinaams Javaans: contact Leiden/KITLV for existing Swadesh data. Adelaar (1991) and Mesthrie may have relevant data. This is a concrete, low-cost study that could be done quickly as a calibration paper.

[ ] Section 4.3 Kalimantan — Niah Cave dates: check latest Barker et al. publications for current understanding of the ~40,000 BP occupation. Use this as the anchor for the low-taphonomy control.

[ ] The 'ghost population' discussion in 6.2 needs aDNA citation — specifically Skoglund & Mathieson (2018) review and McColl et al. (2018) Science paper on ISEA ancient genomes.

[ ] NusaRC database: this is a significant infrastructure project that could be a standalone grant application. Consider whether to present it as a component of Paper 7 or as a separate data paper — Data in Brief or Journal of Open Archaeology Data.

[ ] Journal target: the integration of linguistics + genetics + archaeology suggests PNAS, Current Biology, or Science Advances for reach; alternatively Journal of World Prehistory for specialist audience.
